

DAA Practical 9 summary and conclusion

Summary

Prim's Algorithm is a **greedy algorithm** used to find the **Minimum Spanning Tree (MST)** of a connected weighted graph. It starts from any vertex and repeatedly selects the **minimum-weight edge** that connects a selected vertex to an unselected vertex. The process continues until all vertices are included in the MST.

Conclusion

Prim's Algorithm helps to connect all vertices of a graph with **minimum total cost** and without forming cycles. It is useful in problems such as **network design, road connections, and communication systems**. The Python program successfully finds the MST and calculates its total cost.
